ABSTRACT. SAFRAN and Crocus are simulation systems developed at the Centre d'Études de la Neige, the snow research department of Météo-France. SAFRAN analyzes weather parameters relevant to snow on the ground, and Crocus simulates the build-up of the snowpack. In this study, simulated snow depths and measured snow depths at three locations in Iceland were compared. The main study was performed for the Hveravellir weather station located 640 m a.s.l. in central Iceland. The results from three winters, 1994–97, were analyzed. In Iceland the “Alpine” version of the models systematically underestimated the snow depth and density of the snowpack. Corrections for the effect of wind on snow density and on precipitation measurements led to significant improvements in simulated snow depths. The simulations are sensitive to the threshold temperature between snow and rain. The remaining problems in simulating the snowpack are mainly related to transport of snow by wind, which is not accounted for in the models, and to some extent to melting and sublimation in strong winds.

INTRODUCTION

Models have been developed at the Centre d'Études de la Neige, the snow research department of Météo-France, to simulate the snow cover and forecast avalanche danger, as described by Brun and others (1989), Durand and others (1998, 1999) and Giraud and others (1998). The inputs to the models are daily meteorological observations as well as an analysis and forecasts from a meteorological model. SAFRAN (Système d'Analyse Fournissant des Renseignements Atmosphériques à la Neige) estimates relevant meteorological parameters that affect snowpack evolution, such as air temperature, wind speed, precipitation, air humidity, cloudiness, longwave radiation, direct and scattered solar radiation. The results of SAFRAN are used by Crocus to simulate the physical processes inside the snowpack and its stratigraphy. The SAFRAN and Crocus (SC) models have been in operational use in the French Alps since 1992 and are also used in the Pyrenees. They have been improved using feedback from snow observers and observational data during that period.

It is important to gain better understanding of the snow cover, forecast its development and further develop the models for different circumstances. SAFRAN and Crocus are being tested and adapted to Iceland's oceanic climate and strong winds. They were previously tested in maritime climatic conditions in Canada (Mingo and McClung, 1998) and Norway (Petersen, 1998). In Canada they were tested in an area with a snow climate transitional between maritime and continental type, and also in an area with a maritime snow climate with mild temperatures and deep snowpacks. The snow cover lasted throughout the winter. The densities were underestimated in one of the locations, due to wind and gusts of wind. Good agreement was obtained between simulated and measured snow depth.

In Norway Crocus was tested at locations near the Arctic Circle, approximately 10 km from the outer coastline. The snow cover lasted throughout the winter, although some periods of melting occurred, and the wind speed normally did not exceed 5 m s^{-1} . The models generally performed well, but difficulties arose during periods when temperatures were changing from below to above freezing and vice versa.

More than 10 towns in Iceland are located in areas with avalanche risk. After two major avalanche catastrophes in 1995, the Icelandic Meteorological Office became responsible for the evacuation of towns and villages during avalanche danger. Precipitation intensity and subsequent snow accumulation, as well as snow stratigraphy, have been primary parameters used for avalanche warning in Iceland. Usually the most severe danger develops during snowstorms lasting for several days. Under such conditions it is difficult to obtain information about the development of the snowpack in the field. A model to simulate the snow cover and thus help forecast avalanche danger would be a very important means of improving avalanche warnings.

CLIMATE AND OBSERVATIONAL DATA

Iceland is an island in the North Atlantic (Fig. 1) with a humid, oceanic climate. Rapid weather changes related to frequent extratropical cyclones are common. Lows are frequently in the vicinity or moving across the country. The frontal areas often bring strong winds and heavy precipitation. The weather is more unstable than in the French Alps where the models were originally developed and tested.

The main study was done for Hveravellir (Fig. 1), a manned weather station located in the central highland of Iceland. Hveravellir is relatively far from the coast, and the

Fig. 1. Iceland, location of the three weather observation stations used in the tests.

temperature is usually below zero during winter (Table 1). The temperature conditions at Hveravellir are thus more similar to those in the operational areas in the French Alps than to those on the Icelandic coast.

The models were also tested for two manned coastal weather stations in north and northwest Iceland. The station at Sauðanesviti lies on a peninsula close to the town of Siglufjörður, and the other station is located in Bolungarvík; both towns are endangered by avalanches. The mountains above these towns are 600–700 m high.

At Sauðanesviti, synoptic weather observations are made every 3 hours except at 0300 GMT (Greenwich mean time), and at Hveravellir and Bolungarvík every 3 hours, day and night. The measured precipitation is summarized over 24 hours.

At Hveravellir, snow depth is measured at 1100 GMT at 35 permanent stakes. The average depth at all the stakes is used in this study. Due to strong winds, spatial variation of snow depth is large, but the location of the stakes is such that an average snow depth should provide a reasonably accurate estimate of the snow depth in the area. Some snow-density measurements are also available from Hveravellir.

At Sauðanesviti and Bolungarvík, the quality of daily snow observations is not as high as at Hveravellir, but still based on an average at several locations.

The three winters

All the stations have a windy climate. Winter 1994/95 was

Table 1. Test stations

Observation station	Elevation m a.s.l.	Period (1 Aug. –31 July)	T_{avg} in Nov.	T_{avg} in Feb.	T_{avg} in Apr.	r_{year} = measured precipit.	Max. snow depth
			°C	°C	°C	mm a ⁻¹	cm
Hveravellir	641	1994/95	-3.6	-8.9	-4.7	1414	121
		1995/96	-3.5	-6.5	-1.3	1081	60
		1996/97	-8.4	-7.1	-1.7	1172	105
Sauðanesviti	30	1994/95	2.2	-2.4	-0.3	1860	86
		1995/96	2.0	-0.5	2.3	1727	28
		1996/97	-1.0	-1.5	2.3	1365	66
Bolungarvík	23	1994/95	0.7	-3.1	-0.8	744	63
		1995/96	1.5	-1.7	1.2	1295	30
		1996/97	-2.0	-2.8	1.8	1381	78

unusually severe in north and northwest Iceland. The average wind speed was 7.7 m s^{-1} at Sauðanesviti (maximum 29 m s^{-1}) and 8.7 m s^{-1} at Hveravellir (maximum 41 m s^{-1}). Further information about temperature, measured precipitation and maximum snow depth during the three test winters is shown in Table 1.

Winter 1995/96 had little snow overall, except in October when an avalanche cycle lasted for several days in the north and northwest. The snow accumulation during this avalanche period was, however, poorly represented at the coastal stations.

Winter 1996/97 was considered average with respect to snow conditions.

Snow densities

Jóhannesson and others (1998) compared conditions in Iceland and Switzerland, and found that the density of a stable mid-winter snowpack in north Iceland is $400\text{--}450 \text{ kg m}^{-3}$, substantially higher than in the Swiss Alps. They also found that snow density in Iceland, unlike that in Switzerland, appears to be relatively independent of altitude. The densities measured in Iceland were similar to those measured in Grasdalen, Norway.

Measurements in fracture lines of avalanches have shown high densities as well. Two days after the Flateyri avalanche in northwest Iceland in 1995, the density in the fracture line was 360 kg m^{-3} (Haraldsdóttir, 1998). The snow accumulated during a storm in which measured wind speed in the mountains reached 48 m s^{-1} (10 min average), but the average wind speed during the 3 days prior to the avalanche was 30 m s^{-1} . The temperature close to the starting zone was -4° to -10°C during that period.

TESTS OF SAFRAN AND CROCUS

The SC models were used to simulate snowpack development at the previously described locations in Iceland during three winters. Observations from the three stations were used as input, together with analysis of relevant atmospheric parameters from the European Centre for Medium-range Weather Forecasts.

The ‘‘Alpine’’ version of the SC models, as described by Brun and others (1989) and Durand and others (1998, 1999), was tested with Icelandic data by comparing simulated snow depths from the models with the observed snow depth. Adjustments were made to take into account the impact of high winds on the density of the snowpack and precipitation-measurement errors. Studies of snow-depth sensitivity to the value of the threshold temperature between snow and rain were also conducted.

Snow densities

Strong wind leads to branches breaking off the snow crystals, creating small fine-grained snow, so the snow on the ground becomes more dense. The impact of temperature and wind on the density of new snow in Crocus is calculated by the equation

$$\rho = k_1 + k_2(T - 273.15) + k_3U^{k_4}, \quad (1)$$

where ρ is density, k_1 , k_2 , k_3 and k_4 are constants, T is temperature and U is the wind speed. In the sensitivity tests using the Icelandic data, k_3 was changed from 0.026 to 0.04, and k_4 from 0.5 to 0.75. The density therefore increased more in the new simulations with increased wind speed than it did with the original values of the constants.

Fig. 2. Precipitation-correction factor for snow, k_s , for Svalbard I, “Førland” (Førland and others, 1996; Førland and Hanssen-Bauer, 2000) and Sigurdsson (1990). According to Svalbard I and Førland, k_s increases with decreasing temperature down to -12°C and also increases with increasing wind speed up to 7 m s^{-1} . Sigurdsson suggested a constant of 2 for Hveravellir.

Precipitation corrections

It is generally accepted that measured precipitation in wind and temperature below 0°C gives an underestimate of the “ground true” precipitation. The most important source of error is the wind, which directly affects the flow around the gauge, though some types of gauges have wind shields to reduce this effect. Snowdrift also affects the measurements. Wetting of the interior of the rain gauge and evaporation can also be important.

A simple precipitation-correction method employs an equation of the form

$$P_c = k(P_m + \Delta P_w + \Delta P_E), \quad (2)$$

where P_c is “ground true” precipitation, k is a correction factor, P_m is measured precipitation, ΔP_w is a correction for wetting of the rain gauge and ΔP_E is a correction for loss from evaporation (e.g. Sigurdsson, 1990; Førland and Hanssen-Bauer, 2000). The correction factor, k , is a function of temperature and wind speed at the wind-gauge level.

Three precipitation-correction methods have been studied to find the best way of estimating the precipitation-correction factor k .

A Nordic study was performed at Jokioinen, southwest Finland (Førland and others, 1996; Førland and Hanssen-Bauer, 2000), and the results were correction factors for solid (k_s) and liquid (k_l) precipitation. According to this Nordic study, the measured winter precipitation may be $<50\%$ of the true amount in wind-exposed coastal and mountainous areas in the Nordic countries.

A further study was made in Svalbard ($78^\circ56' \text{ N}$, $11^\circ53' \text{ E}$) which reached higher wind speeds (Hanssen-Bauer and others, 1996), and the correction method Svalbard I was among the results. Here, as in the Nordic study, there were only a few occurrences of snowfall in strong wind.

Sigurdsson (1990) studied runoff and precipitation measurements in Iceland. He suggested a correction factor of 2 for solid precipitation or snow for Hveravellir as an average for a year, and 1.32 for liquid precipitation or rain.

The correction factor for solid precipitation for the Svalbard I and Førland methods is a function of temperature, T_g , and wind speed, v_g , at the height of the rain gauge.

Fig. 3. Observed snow depth, simulated snow depth without correction (original model) and examples of simulated snow depth with precipitation correction for various limits of the critical wind speed and the Icelandic density formulation at Saudanesviti, 1994/95.

For liquid precipitation it was a function of the wind speed and the precipitation intensity. The limits set for the formulation of the precipitation-correction factor were the ones reached at the test site in Finland during the measurements $T \geq -12^\circ\text{C}$ and $v_g \leq 7\text{ m s}^{-1}$.

Figure 2 shows the three precipitation-correction models. They are plotted against wind speed, at $T = -5^\circ\text{C}$. The figure also shows the correction factor of 2 suggested by Sigurdsson. Similarly, average long-term values of 1.15 (liquid precipitation) and 1.85 (solid precipitation) have been suggested for Svalbard by Førland and Hanssen-Bauer (2000).

For low wind speeds the Svalbard I and Førland curves are almost identical, while for wind speeds greater than about 4 m s^{-1} Svalbard I gives lower values of the correction factor. For values close to 7 m s^{-1} , both models give a correction factor of 3–4 and even greater for lower temperatures. With average wind speeds of $>8\text{ m s}^{-1}$, both the Svalbard I and Førland models would give precipitation amounts in Hveravellir that are far beyond the Sigurdsson model. Bearing in mind that the correction curves in the Svalbard I and especially in the Førland model are based on only a limited number of observations at high wind speeds and that Sigurdsson’s study relates the measured precipitation to the actual runoff in the Hveravellir area, the present study employs a correction factor based on the Svalbard I model for wind speed at gauge level v_g , but only up to a critical wind speed. For greater wind speeds the correction factor has the same value as for the critical wind speed. Some sensitivity tests of the value of the wind-speed limit were conducted (Fig. 3). They are discussed later in this paper.

Estimation of the wind at the height of the rain gauge is based on observations at 10 m height and a local study of the average vertical profile of wind speed (Arason, 1998) stating that

$$V_2 V_1 = (H_2/H_1)^{0.16}, \quad (3)$$

where V_2 is the speed at height H_2 and V_1 is the speed at height H_1 .

This gives a wind speed at gauge level (v_g), which is 1.5 m above the ground, of 74% of the wind speed at 10 m height.

The threshold temperature, T_c

A study of synoptic weather observations (Ólafsson and Haraldsdóttir, 2000) over a period of 30 years showed that

Fig. 4. Simulated snow depth for various threshold temperatures between snow and rain, T_c , and the Alpine density formulation at Sauðanesviti 1994/95. The simulations included a precipitation correction.

the threshold temperature between snow and rain (T_c) has large spatial variation in Iceland, ranging from about 0.5° to 2°C . This large variability is due to differences in the proportion of stratiform and convective precipitation and variations of the static stability of the low-level air masses, which is largely influenced by the proximity of a warm ocean and mountains. T_c was estimated to be 1.0°C at Hveravellir and Sauðanesviti, as in the original models for the Alps, but 1.5°C at Bolungarvík.

RESULTS

Figure 4 shows the effect of the threshold temperature on snow-depth simulations. The maximum difference in the simulations in the figure is 29 cm, or 34% of the maximum observed snow depth. The temperature at the coastal stations is close to 0°C more often than at Hveravellir, so they are more sensitive to the value of T_c .

Table 2 shows observed and simulated densities of the snowpack at Hveravellir. The observed density is formulated with the ‘‘Alpine’’ values of k_3 and k_4 , while simulated density uses the ‘‘Icelandic’’ values of $k_3 = 0.04$ and $k_4 = 0.75$. The models greatly underestimate the density, and a considerable improvement is achieved by increasing the wind effects on density. The density on 1 November 1994 is, however, overestimated by the models, mainly because the snow pits do not correctly represent the snowpack.

In Table 2, the average difference between observed and

Table 2. Observed and simulated densities, from the original (Alpine) version of Crocus and from the ‘‘Icelandic’’ Crocus (using $k_3 = 0.04$ and $k_4 = 0.75$ in Equation (1)). Precipitation correction is employed

Fig. 5. Observed snow depth, simulated snow depth without correction (original model) and simulated snow depth with the Icelandic density formulation and precipitation correction for various critical wind-speed limits at Hveravellir, 1994/95.

simulated density is 21% for the Alpine version, while after the density corrections (Icelandic density) the difference is 17%. If only the period of thick snowpack is considered, i.e. excluding 1 November 1994, the corresponding differences are 22% and 11%, which is indeed a good improvement.

The precipitation corrections proved to be important for the windy climate. After setting the threshold temperature between snow and rain, as explained in the previous section, and including the above density correction, the precipitation was corrected. The simulated snow depth is very sensitive to the precipitation correction, as can be seen in Figure 3 (Sauðanesviti 1994–95) which shows the Svalbard I model applied up to different critical wind speeds. The bottom curve is the original model, but all the other curves include both density correction and precipitation correction. Critical wind speed of 5 m s^{-1} gave the best overall results when comparing observed and simulated snow depths.

Figure 5 is from Hveravellir, 1994–95, and shows that the simulated snow depths using precipitation correction with critical wind speed at 7 m s^{-1} are high compared with the observed snow depth. Most of the simulations are good except for 22 December, when a mixture of rain and snow was simulated only as snow in the models. The increase in snow depth was 2 cm in the observations but 15 cm in the models, a difference that continued throughout the snow season. Figure

Fig. 6. A result of the model adaptation for Hveravellir, 1996/97: observed snow depth, simulated snow depth with precipitation correction with a critical wind-speed limit of 5 m s^{-1} and the Icelandic density formulation, and simulated snow depth without correction (original model).

Fig. 7. A result of the model adaptation for Bolungarvík 1996/97: observed snow depth, simulated snow depth without correction and simulated snow depth with the Icelandic density formulation and precipitation correction with a critical wind-speed limit of 5 m s^{-1} .

6 shows the observed and simulated snow depth during the entire winter season 1996/97 at Hveravellir. The importance of the precipitation correction is evident, but so is an underestimation by the models of the melting of the snowpack in the spring.

Figure 7 shows the snow depth at Bolungarvík in spring 1997. The simulations do not reproduce the two snow-depth maxima. A close study of the associated weather revealed

that wind directions were particularly favourable for snow transport and accumulation at the observation site. The accumulation appears to be poorly represented in precipitation measurements and consequently also in the simulations.

The overall results of the simulations of snow depth before and after density and precipitation corrections at Hveravellir, Sauðanesvíti and Bolungarvík are shown in Figures 8–10. The improvement due to the corrections is considerable at Hveravellir and Sauðanesvíti. Bolungarvík is the hardest one to simulate. The largest remaining errors are related to wrong melting and sublimation in the models and snowdrift.

DISCUSSION

There is a satisfying overall agreement between observed and simulated snow depth at Hveravellir and Sauðanesvíti after changing the formulation for the density of new snow and correcting the precipitation. Apart from melting and sublimation in strong winds and snowdrift, the inaccuracy of the snow observations becomes a factor limiting further development of the models for operational use in Iceland. In some cases, such as at in Bolungarvík in spring 1997, it is reasonable to believe that the models give a better picture of the average snow depth over a large area than do the observations, since they do not simulate the effects of snowdrift.

The models generally performed better at Hveravellir than at the two coastal stations. The coastal regions are char-

Fig. 10. Results of the adaptation of the models at Bolungarvík, 1995–97: simulated snow depth vs observed snow depth. (a) The Icelandic density formulation and precipitation correction with a critical wind-speed limit of 5 m s^{-1} . (b) Original (Alpine) model.

acterized by periods of strong and warm winds that lead to melting and sublimation which is not well represented by the models, as seen at Sauðanesvíti in late March 1995 (Fig. 3).

Rapid temperature changes associated with heavy precipitation are another characteristic of the climate in Iceland. In some cases when the temperature is passing the threshold value of temperature for solid/liquid precipitation, the models show relatively large errors. This feature was more obvious at the coastal stations with the rapidly changing temperatures around 0°C than at Hveravellir, where temperatures are $<0^\circ\text{C}$ for most of the winter. Solving such problems requires continuous measurements of precipitation and temperature, which hopefully will be available soon.

The models do not take into account snowdrift, or transport of snow by wind. In a climate where strong winds are frequent this leads to errors. Taking the average of observed snow depth at many stakes reduces these errors. Further modelling efforts are being made for snowdrift (Durand and others, 2001). Although a simple model for correcting drifting snow is being developed, simulating the snowdrift in a complex terrain remains a major challenge.

GENERAL CONCLUSIONS AND FUTURE WORK

Initial results are promising for the possible use of the models in Iceland. The results improved by adjusting to the unstable, windy climate which is quite different from that in the Alps.

Applying a correction for precipitation measured in strong wind made the most important improvement, together with corrections for wind effect on new-snow density. Other wind effects, such as melting and sublimation during periods of strong wind and snow transport, still remain to be simulated.

In the future, information from snow pits in avalanche towns in the neighbourhood of the weather stations will be compared with the simulation of the snowpack structure, such as densities, and crystal morphology. This should lead to further improvement of the models.

The models have now been set up to be tested in daily operation for avalanche warning, using the forecast of increase in snow depth as a warning sign at the first stage. Applying the results of the present study will lead to significant improvement of the models in this context.

ACKNOWLEDGEMENTS

The cooperation between workers from France and Iceland is promising for the future development of the SC models for the Icelandic climate. C. Fierz and M. M. Magnússon gave valuable advice and made helpful comments on the paper, and E. Førland advised on the section on precipitation correction. An anonymous reviewer also made many useful suggestions and comments. L. Tracy helped with the language.
